Abstract

This document describes the structures making up the version 1.2 of the VOTable standard, which supersedes the version 1.1 of 08 August 2004. The differences between versions 1.1 and 1.2 are summarized in section 8. The main part of this document describes the adopted part of the VOTable standard; it is followed by appendices presenting extensions which have been proposed and/or discussed, but which are not part of the standard.

Status of this document

This is an IVOA Proposed Recommendation made available for public review. It is appropriate to reference this document only as a recommended standard that is under review and which may be changed before it is accepted as a full recommendation.

This proposed recommendation is made available for public review. Comments to this document should be sent to votable@ivoa.net, a mailing list with a [public archive](#). It is appropriate to reference this document only as a recommended standard that is under review and which may be changed before it is accepted as a full recommendation.

A list of current IVOA Recommendations and other technical documents can be found at <http://ivoa.net/Documents/>

Acknowledgments

This document is based on the W3C documentation standards, but has been adapted for the IVOA.

1 Introduction

The VOTable format is an XML standard for the interchange of data represented as a set of tables. In this context, a table is an unordered set of rows, each of a uniform structure, as specified in the table description (the table *metadata*). Each row in a table is a sequence of table cells, and each of these contains either a primitive data type, or an array of such primitives. VOTable is derived from the Astrores format [1], itself modeled on the FITS Table format [2]; VOTable was designed to be close to the FITS Binary Table format.

1.1 Why VOTable?

Astronomers have always been at the forefront of developments in information technology, and funding agencies across the world have recognized this by supporting the Virtual Observatory movement, in the hopes that other sciences and business can follow their lead in making online data both *interoperable* and *scalable*.

VOTable is designed as a flexible storage and exchange format for tabular data, with particular emphasis on astronomical tables.

Interoperability is encouraged through the use of standards (XML). The XML fabric allows applications to easily validate an input document, as well as facilitating transformations through XSLT (eXtensible Style Language Transformation) engines.

Grid Computing

VOTable has built-in features for big-data and Grid computing. It allows metadata and data to be stored separately, with the remote data linked. Processes can then use metadata to ‘get ready’ for their input data, or to organize third-party or parallel transfers of the data. Remote data allow the metadata to be sent in email and referenced in documents without pulling the whole dataset with it: just as we are used to the idea of sending a pointer to a document (URL) in place of the document, so we can now send metadata-rich pointers to data tables in place of the tables themselves. The remote data is referenced with the URL syntax `protocol://location`, meaning that arbitrarily complex protocols are allowed.

When we are working with very large tables in a distributed-computing environment (“the Grid”), the data stream between processors, with flows being filtered, joined, and cached in different geographic locations. It would be very difficult if the number of rows of the table were required in the header – we would need to stream in the whole table into a cache, compute the number of rows, then stream it again for the computation. In the Grid-data environment, the component in short supply is not the computers, but rather these very large caches. Furthermore, these remote data streams may be created dynamically by another process or cached in temporary storage: for this reason VOTable can express that remote data may not be available after a certain time (**expires**). Data on the net may require authentication for access, so VOTable allows expression of password or other identity information (the **rights** attribute).

Data Storage: Flexible and Efficient

The data part in a VOTable may be represented using one of three different formats: TABLEDATA, FITS and BINARY. TABLEDATA is a pure XML format so that small tables can be easily handled in their entirety by XML tools. The FITS binary table format is well-known to astronomers, and VOTable can be used either to encapsulate such a file, or to re-encode the metadata; unfortunately it is difficult to stream FITS, since the dataset size is required in the header (NAXIS2 keyword), and FITS requires a specification up front of the maximum size of its variable-length arrays. The BINARY format is supported for efficiency and ease of programming: no FITS library is required, and the streaming paradigm is supported.

We hope that VOTable can be used in different ways, as a data storage and transport format, and also as a way to store metadata alone (table structure only). In the latter case, we can imagine a VOTable structure being sent to a server, which can then open a high-bandwidth connection to receive the actual data, using the previously-digested structure as a way to interpret the stream of bytes from the data socket.

VOTable can be used for small numbers of small records (pure XML tables), or for large numbers of simple records (streaming data), or it can be used for small numbers of larger objects. In the latter case, there will be software to spread large data blocks among multiple processors on the Grid. Currently the most complex structure that can be in a VOTable Cell is a multidimensional array.

1.2 XML Conventions

VOTable is constructed with **XML** (extensible Markup Language), a powerful standard for structured data throughout the Internet industries. It derives from SGML, a standard used in the publishing industry and for technical documentation for many years. XML consists of *elements* and payload, where an element consists of a *start tag* (the part in angle brackets), the payload, and an *end tag* (with angle brackets and a slash). Elements can contain other elements. Elements can also bear **attributes** (keyword-value combinations).

The payload may be in two forms: parsed or unparsed character data. Examples are:

```
<text>Fran&#231;ois</text>
<text><![CDATA[ a & (b <= c) ]]></text>
```

In the first example, the sequence `ç` is interpreted as part of the ISO/IEC 10646 character set (Unicode), and translates to an accented character, so that the text is “François”. The second example uses the special `CDATA` sequence so that the characters `<`, `>`, and `&` can be used without interpretation; in this case, any ASCII characters are allowed except the terminating sequence `]]>` For more information, see any book on XML.

1.3 Syntax policy

Following the general XML rule, element and attribute names are case-sensitive and have to be used with the specified capitalisation. For VOTable, we have adopted the convention that element names are spelled in uppercase and attribute names in lowercase (with an exception for the **ID** attribute). Element and attribute names are further distinguished in this paper by being typed with a `fixed-width` font.

2 Data Model

In this section we define the data model of a VOTable, and in the next sections its syntax when expressed as XML. The data model of VOTable can be expressed as:

VOTable	=	hierarchy of Metadata + associated TableData , arranged as a set of Tables
Metadata	=	Parameters + Infos + Descriptions + Links + Fields + Groups
Table	=	list of Fields + TableData
TableData	=	stream of Rows
Row	=	list of Cells
Cell	=	$\left\{ \begin{array}{l} \text{Primitive} \\ \text{or variable-length list of Primitives} \\ \text{or multidimensional array of Primitives} \end{array} \right.$
Primitive	=	integer, character, float, floatComplex, etc (see Table 1 below).

Metadata is divided into that which concerns the table itself (parameters), and the definitions of the fields (or column attributes) of the table. Each **FIELD** represents the metadata that can be found at the top of the column in a paper version of the table: in the example introduced in section 3.1 below, the first **FIELD** has its **name** attribute set to “**RA**”. The Field can be thought of as a class definition, and the table cells below it are the instances of that class.

A parameter (**PARAM**) is similar to a **FIELD**, except that it has a **value** attribute. Parameters can be seen as “constant columns”, containing for instance FITS keywords or any other information pertaining to the table itself or its environment, such as the **Telescope** parameter in the example of section 3.1.

An informative parameter (**INFO**) (see section 4.8) is a restricted form of the **PARAM** — it is always understood as a *string* (i.e. **datatype**="char" and **arraysize**="*" are *implied*).

The ordered list of Fields at the top of the table thus provides a template for a Row object (also called a *record*). The template allows interpretation of the data in the Row. The record is a set of Cells, with the number and order of Cells the same for each Row, and the same as the number of Fields defined in the Metadata.

In VOTable, there is generally no advance specification of the number of rows in the table: this is to allow streaming of large tables, as discussed above. However, if the number of rows is known, it may be specified in a dedicated **nrows** attribute.

From Version 1.1, columns may be logically grouped, so that it is possible to define table substructures made of column associations. Such an association is declared as a **GROUP**, which typically contains column references (**FIELDref**) and associated parameters (**PARAM**).

2.1 Primitives

datatype	Meaning	FITS	Bytes
"boolean"	Logical	"L"	1
"bit"	Bit	"X"	*
"unsignedByte"	Byte (0 to 255)	"B"	1
"short"	Short Integer	"I"	2
"int"	Integer	"J"	4
"long"	Long integer	"K"	8
"char"	ASCII Character	"A"	1
"unicodeChar"	Unicode Character		2
"float"	Floating point	"E"	4
"double"	Double	"D"	8
"floatComplex"	Float Complex	"C"	8
"doubleComplex"	Double Complex	"M"	16

Table 1: List of the Primitives (*details in section 6*)

Each Cell is composed from Primitives, each of which is a datatype of fixed-length binary representation, as listed in Table 1. Cells may consist of a single Primitive (this is the default), or of an *array* (eventually multidimensional) of Primitives (see section 2.2).

Except for the Bit type, each primitive has the fixed length in bytes given in Table 1. Bit scalars and arrays are stored in the minimum number of bytes feasible (so that b bits take the integer part of $(b + 7)/8$ bytes). These primitives are described in more detail in section 6.

VOTables support two kinds of characters: ASCII 1-byte characters and Unicode (UCS-2) 2-byte characters. Unicode is a way to represent characters that is an alternative to ASCII. It uses two bytes per character instead of one, it is strongly supported by XML tools, and it can handle a large variety of international alphabets. Therefore VOTable supports not only ASCII strings (**datatype="char"**), but also Unicode (**datatype="unicodeChar"**). Note that strings are not a primitive type: strings are represented in VOTable as an array of characters.

2.2 Columns as Arrays

A table cell can contain an *array* of a given primitive type, with a fixed or variable number of elements; the array may even be multidimensional. For instance, the position of a point in a 3D space can be defined by the following:

```
<FIELD ID="point_3D" datatype="double" arraysize="3"/>
```

and each cell corresponding to that definition must contain exactly 3 numbers. An asterisk (*) may be appended to indicate a *variable* number of elements in the array, as in:

```
<FIELD ID="values" datatype="int" arraysize="100*"/>
```

where it is specified that each cell corresponding to that definition contains 0 to 100 integer numbers. The number may be omitted to specify an unbounded array (in practice up to $\simeq 2 \times 10^9$ elements).

A table cell can also contain a *multidimensional array* of a given primitive type. This is specified by a sequence of dimensions separated by the x character, with the first dimension changing fastest; as in the case of a simple array, the last dimension may be variable in length. As an example, the following definition declares a table cell which may contain a set of up to 10 images, each of 64x64 bytes:

```
<FIELD ID="thumbs" datatype="unsignedByte" arraysize="64x64x10*"/>
```

Strings, which are defined as a set of characters, can therefore be represented in VOTable as a fixed- or variable-length array of characters:

```
<FIELD name="unboundedString" datatype="char" arraysize="*" />
```

A 1D array of strings can be represented as a 2D array of characters, but given the logic above, it is possible to define a variable-length array of fixed-length strings, but not a fixed-length array of variable-length strings. A convention to express an array of variable-length strings was proposed (see section A.3) but is not part of this standard.

2.3 Compatibility with FITS Binary Tables

VOTable is closely compatible with the FITS Binary Table format. Henceforth, we shall abbreviate “FITS Binary Table and its Conventions” simply by the word “FITS”. Given a FITS file that represents a binary table, the header may be converted to VOTable, with a pointer to the original file, or with the original file included directly in VOTable. Since the original file is still present, it is clear that no data has been lost. A **PARAM** element can be used to hold any FITS keyword with its value and comment string.

We might ask two more significant questions, about how much of the FITS header and data can be represented in VOTable. The answer is that there is considerable overlap.

For instance, the recommended formatting of the data for an edition of the data is expressed by the non-mandatory TDISP keyword: for example F12.4 means 12 characters are to be used, and 4 decimal places. This has been converted in VOTable as the attributes **width** and **precision** which, connected with **datatype**, are semantically identical to the TDISP keyword.

What can FITS do but not VOTable?

FITS has a complex semantics, with many conventions (see *e.g.* the [Registry of FITS Conventions](#) [11]) which have been developed mainly to be able to cope with the increasing complexity of the astronomical instrumentation. In the frame of the *Virtual Observatory* the complexity is described by means of *data models*, and from its version 1.1, VOTable can refer to these data models by means of the **utype** attribute described in section 4.6.

What can VOTable do but not FITS?

VOTable supports separating of data from metadata and the streaming of tables, and other ideas from modern distributed computing. It bridges two ways to express structured data: XML and FITS. It tries (through the UCD – see section 4.5) to express formally the semantic content of a parameter or field. It has the hierarchy and flexibility of XML: using **GROUP** elements introduced in version 1.1, columns in a VOTable can be grouped in arbitrarily complex hierarchies; and the ID attribute can be used in XML to enable what are essentially pointers. FITS does not handle Unicode (extended alphabet) characters.

It should be noticed that the transformation of FITS to VOTable is meant to be reversible: any FITS table can be converted to a VOTable without loss of information and the resulting VOTable can be converted back to a FITS table also without loss of information. However, it is possible to create new VOTables which cannot be converted to FITS tables without loss of information.

3 The VOTable Document Structure

The overall VOTable document structure is described and controlled by its [XML Schema](#) referenced at the top. That means that documents claiming to represent VOTables must include the reference to the VOTable schema, and pass through W3C XML Schema validators without error; notice that the validation is a necessary, *but not sufficient*, condition for correctness. The XML Schema of this version 1.2 is included in appendix B, and is illustrated in section 7.

An example is used here to illustrate the components of a VOTable document described in the following sections. Basically, a VOTable document consists of a single all-containing element called **VOTABLE**, which contains descriptive elements and global definitions (**DESCRIPTION**, **GROUP**, **PARAM**, **INFO**), followed by one or more **RESOURCE** elements. Each Resource element contains zero or more **TABLE** elements, and possibly other **RESOURCE** elements.

The **TABLE** element, the actual heart of VOTable, contains a description of the columns and parameters (described in section 4) followed by the data values (described in section 5).

3.1 Example

This simple example of a VOTable document lists 3 galaxies with their position, velocity and error, and their estimated distance. It contains a reference to the *Space-Time Coordinate* data model (*STC*, A. Rots [9]) implicitly used to specify the system of coordinates used to locate the observed galaxies in the sky: this is an essential difference from the previous versions of *VOTable* which made use of a **COOSYS** element for this specification.

```
<?xml version="1.0"?>

      </FIELD>
      <DATA>
        <TABLEDATA>
          <TR>
            <TD>010.68</TD><TD>+41.27</TD><TD>N 224</TD><TD>-297</TD><TD>5</TD><TD>0.7</TD>
          </TR>
          <TR>
            <TD>287.43</TD><TD>-63.85</TD><TD>N 6744</TD><TD>839</TD><TD>6</TD><TD>10.4</TD>
          </TR>
          <TR>
            <TD>023.48</TD><TD>+30.66</TD><TD>N 598</TD><TD>-182</TD><TD>3</TD><TD>0.7</TD>
          </TR>
        </TABLEDATA>
      </DATA>
    </TABLE>
  </RESOURCE>
</VOTABLE>
```

This simple **VOTABLE** document shows a single **RESOURCE** made of a single **TABLE**; the table is made of 6 columns, each described by a **FIELD**, and has one additional **PARAM** parameter (the Telescope). The actual rows are listed in the **DATA** part of the table, here in XML format (introduced by **TABLEDATA**); each cell is marked by the **TD** element, and follow the same order as their **FIELD** description: *RA*, *Dec*, *Name*, *RVel*, *e_RVel*, *R*.

3.2 name, ID and ref attributes

Most of the elements defined by VOTable may or have to bear *names*, like a **RESOURCE**, a **TABLE**, a **PARAM** or a **FIELD**. The contents of the **name** attribute is defined as a *token* XML type, that is a string of characters where the blanks and spaces are not meaningful (no leading or trailing spaces, no multiple spaces): **name="NVSS flux(1.4GHz)"** represents therefore a valid name.

The **ID** and **ref** attributes are defined as XML types *ID* and *IDREF* respectively. It means that the contents of **ID** is an *identifier* which must be unique throughout a VOTable document, and that the contents of the **ref** attribute represents a reference to an identifier which must exist in the VOTable document. In other terms, if **ref="myStar"** is found in one element, there must exist an element in the same document with the **ID="myStar"** attribute. The XML standard moreover specifies that an *ID* type is a string beginning with a letter or underscore (`_`), followed by a sequence of letters, digits, or any of the punctuation characters `.` (dot), `-` (dash) or `_` (underscore), but not the `:` (colon). Therefore **ID="1"** is *not* valid, but **ID="_1"** or **ID="ref.1"** are both valid.

The **ID** attribute is therefore required in the elements which *have to be referenced*, but the elements having an **ID** attribute need not to be referenced. In VOTable1.2, it is moreover recommended to place the **ID** attribute *before* referencing it whenever possible.

While the **ID** attribute has to be unique in a VOTable document, the **name** attribute need not. It is however recommended, as a good practice, to assign unique names within a **TABLE** element. This recommendation means that, between a **TABLE** and its corresponding closing `/TABLE` tag, **name** attributes of **FIELD**, **PARAM** and optional **GROUP** elements should be all different.

3.3 VOTABLE element

The **VOTABLE** element may contain definitions consisting of a **DESCRIPTION**, followed by any mixture of parameters and informative notes eventually structured in *groups*. These elements represent values which are meaningful over all tables included in a **VOTABLE** document — definitions specific to a **RESOURCE** (section 3.4) or a **TABLE** (section 3.6) are better placed within their most appropriate element.

Note that version 1.0 of VOTable required the usage of a **DEFINITIONS** element holding the VOTable global definitions — this usage is deprecated since the version 1.1

Space and Time coordinates

An essential difference with the version 1.1 of VOTable concerns the way adopted in version 1.2 to describe the *coordinate system*: a dedicated **COOSYS** element was defined in VOTable 1.0, which is deprecated in this version (1.2) in favor of a more generic facility of *referring external data models*.

The coordinates — space and time, and eventually the spectral and redshift parameters — are described in the *STC* model (A. Rots, see [9]), which specifies the various components and systems used in Astronomy to locate the events in time and space with a high accuracy.

From Version 1.2, *VOTable* suggests to make use of the **GROUP** element (section 4.9) and the **utype** attribute (section 4.6) to describe with all the required accuracy the coordinate systems used in the data conveyed in a VOTable. A dedicated note on *Referencing STC in VOTable* [8] describes in more details how to express the coordinate components.

3.4 RESOURCE element

A VOTable document contains one or more **RESOURCE** elements, each of these providing a description and the data values of some logically independent data structure.

Each **RESOURCE** may include the descriptive element **DESCRIPTION**, followed by a mixture of **INFO**, **GROUP** and **PARAM** elements; it may also contain **LINK** elements to provide URL-type pointers that give further information.

The main component of a **RESOURCE** is typically one or more **TABLE** elements – in other terms a **RESOURCE** is basically a set of related tables. The **RESOURCE** is recursive (it can contain other **RESOURCE** elements), which means that the set of tables making up a **RESOURCE** may become a tree structure.

A **RESOURCE** may have one or both of the **name** or **ID** attributes (see section 3.2); it may also be qualified by **type="meta"**, meaning that the resource is *descriptive* only, i.e. does not contain any actual data: no **DATA** element should exist in any of its sub-elements. A **RESOURCE** without this attribute *may* however have no **DATA** sub-element. Finally, the **RESOURCE** element may have a **utype** attribute to link the element to some external data model (introduced in version 1.1, see section 4.6).

3.5 LINK element

The role of the **LINK** element is to provide pointers to other documents or data servers on the Internet through a URL. In VOTable, the **LINK** element may be part of a **RESOURCE**, **TABLE**, **GROUP**, **FIELD** or **PARAM** elements. The **href** attribute of the **LINK** element can comprise any arbitrary protocol, for example "<http://server/file>" or "<bizarre://server/file>". VOTable parsers are not required to understand arbitrary protocols, but are required to understand the following three common protocols: "**file**", "**http**:" and "**ftp**:".

A GLU reference [5] is an additional high-level protocol introduced by a "**glu**:" value of the **href** attribute: this way of referencing a GLU is preferred to the **gref** attribute defined in the original version of VOTable. The **gref** attribute is deprecated since version 1.1.

In the Astroles format, from which VOTable is derived, there is additional semantics for the **LINK** element; the **href** attribute is used as a template for creating URL's. This behavior is explained in appendix A.1, and it represents a possible extension of VOTable.

In addition to the referencing **href** attribute and to the naming **name** and **ID** attributes (see section 3.2), the **LINK** element may announce the mime type of the data it references with a **content-type** attribute (e.g. **content-type**="image/fi) and specify the role of the link by a **content-role** attribute (e.g. **content-role**="doc" for access to documentation).

3.6 TABLE element

The **TABLE** element represents the basic data structure in VOTable; it is made of a description of the table structure (the *metadata*) essentially in the form of **PARAM** and **FIELD** elements (detailed in section 4), followed by the *values* of the described fields in a **DATA** element (detailed in section 5).

The **TABLE** element is always contained in a **RESOURCE** element: in other terms any **TABLE** element has a single parent made of the **RESOURCE** element in which the table is embedded.

The **TABLE** element contains a **DESCRIPTION** element for descriptive remarks, followed by a mixed collection of **PARAM**, **FIELD** or **GROUP** elements which describe a parameter (constant column), a field (column) or a group of columns respectively. **PARAM** and **FIELD** elements are detailed in section 4, and the **GROUP** element is presented in section 4.9.

Furthermore the **TABLE** element may contain **LINK** elements that provide URL-type pointers, exactly like the **LINK** elements existing within a **RESOURCE** element (see section 3.5).

The last element included in a **TABLE** is the optional **DATA** element (see section 5): a table without any actual data is quite valid, and is typically used to supply a complete description of an existing resource e.g. for query purposes. The **TABLE** element may have the naming attributes **name** and/or **ID** (see section 3.2). A **TABLE** may also have a **ref** attribute referencing the ID of another table previously described, which is interpreted as *defining a table having a structure identical to the one referenced*: this facility avoids a repetition of the definition of tables which may be present many times in a VOTable document. It is recommended however that the **ref** attribute references an *empty table* (i.e. a table without a **DATA** part), which avoids any ambiguity about the referencing.

Finally, the **TABLE** element may have a **utype** and **ucd** attribute to specify the table semantics, similarly to the **FIELD** and **PARAM** elements (see section 4.1).

4 FIELDS and PARAMETERS

The atoms of the table structure are represented by **FIELD** and **PARAM** elements, where **FIELD** represents the description of an actual table column, while **PARAM** supplies a value attached to the table, like the **Telescope** in the example of section 3.1. A **PARAM** may be viewed as a **FIELD** which keeps a *constant value* over all the rows of a table, and the only difference in the set of attributes of the two elements is the existence of a **value** attribute in a **PARAM** which does not exist in a **FIELD**.

The **FIELD** elements describe the actual columns of the table; the order in which the **FIELD**s are declared is important, as this order *must* be the same one as the order of the columns in section 5.

A **FIELD** or **PARAM** element may have several sub-elements, including the informational **DESCRIPTION** and **LINK** elements (a possibility of several descriptions and titles were proposed, see appendix A.7); it may also include a **VALUES** element that can express limits and ranges of the values that the corresponding cell can contain, such as minimum (**MIN**), maximum (**MAX**), or enumeration of possible values (**OPTION**).

4.1 Summary of attributes

The valid attributes of a **FIELD** or **PARAM** are:

- the **name** and/or **ID**. The **ID** attribute is required if the field has to be referenced (see section 3.2). It may help to include the ordinal number of the column in the table in the value of the **ID** attribute as e.g. **ID="col3"** when a single table is involved: the connection to the corresponding column would become more obvious, especially in the FITS data serialization which uses the ordinal column number in the keywords containing the metadata related to that column.
- the **datatype**, which expresses the nature of the data that is described as one of the permitted primitives (see Table 1 and their exact meaning in section 6). This attribute determines how data are read and stored internally; it is *required*.
- the **arraysize** attribute exists when the corresponding table cell contains more than one of the specified datatype, as explained in section 2.2. Note that strings are not a primitive type, and have to be described as an array of characters.
- the **width** and **precision** attributes define the numerical accuracy associated with the data (see section 4.2).
- the **xtype** attribute, added in VOTable1.2, specifies an *extended* (or *external*) datatype. It is meant to give details about the column contents beyond the primitive **datatype**, like timestamps.
- the **unit** attribute specifies the units in which the values of the corresponding column are expressed (see section 4.4)
- the **ucd** attribute supplies a standardized classification of the physical quantity expressed in the column (see section 4.5).
- the **utype** attribute, introduced in VOTable 1.1, is meant to express the role of the column in the context of an external data model (see section 4.6); it is used in the example section 3.1 to specify *which coordinate component* a field represents, in connection with the **ref** attribute.
- the **ref** attribute is used to quote another element of the document in the definition of a **FIELD** or **PARAM**. It is used in the example of section 3.1 to indicate the coordinate system in which the coordinates are expressed (reference to the **GROUP** element which specifies the coordinate frame).
- The **type** attribute is *not* part of this standard, but is reserved for future extensions (see appendix A.1, appendix A.2 and appendix A.4).

In addition, in the **PARAM** element only:

- the **value** attribute which explicits the **PARAMeter**'s value; **value** is a required attribute of the **PARAM** element.

4.2 Numerical Accuracy

The VOTable format is meant for transferring, storing, and processing tabular data, and is not intended for presentation purposes: therefore (in contrast to Astrores) we generally avoid giving rules on presentation, such as formatting. Inevitably however some at least of the data will have to be presented – either as actual tables, or in forms or graphs, etc... Two attributes were retained for this purpose:

- the **width** attribute is meant as a hint to the application about the number of characters to be used for input or output of the quantity.
- the **precision** attribute is meant to express the number of significant digits, either as a number of decimal places (e.g. **precision="F2"** or equivalently **precision="2"** to express 2 significant figures after the decimal point), or as a number of significant figures (e.g. **precision="E5"** indicates a relative precision of 10^{-5}).

The existence and presentation of the special *null* value of a field (when the actual value of the field is unknown) is another aspect of the numerical accuracy, which is part of the **VALUES** sub-element (see section 4.7).

4.3 Extended datatype **xtype**

The **xtype** attribute was added to expand the basic datatype primitives (in Table 1) representing the storage units which are valid in any of the VOTable serialisations, and correspond therefore exactly to the *FITS* definitions. It was introduced to fill the gap existing between the datatypes known by FITS and those required to express queries (Astronomical Data Query Language or ADQL, see [13]) and their results in tabular form (Table Access Protocol or TAP, see [12]).

The `xtype` attribute is typically foreseen as the way to specify that a parameter represents a *timestamp* (an instant in an absolute time frame), materialized by a UTC date/time string following the ISO-8601 standard (YYYY-MM-DDThh:mm:ss eventually followed by a decimal point and fractions of seconds); parameters required to specify a spatial positioning are other likely candidates.

The actual values of the `xtype` attribute are not defined in this VOTable specification; it is expected however that common conventions will be adopted by the various components of the Virtual Observatory, in a way similar to the adoption of the Unified Content Descriptor (section 3.1)

4.4 Units

The quantities in a column of the table may be expressed in some physical unit, which is specified by the `unit` attribute of the `FIELD`. The syntax of the `unit` string is defined in reference [3]; it is basically written as a string without blanks or spaces, where the symbols `.` or `*` indicate a multiplication, `/` stands for the division, and no special symbol is required for a power. Examples are `unit="m2"` for m^2 , `unit="cm-2.s-1.keV-1"` for $cm^{-2}s^{-1}keV^{-1}$, or `unit="erg/s"` for $ergs^{-1}$. The references [3] provide also the list of the valid symbols, which is essentially restricted to the *Système International* (SI) conventions, plus a few astronomical extensions concerning units used for time, angular, distance and energy measurements.

4.5 Unified Content Descriptors

The Unified Content Descriptors (UCD) can be viewed as a hierarchical glossary of the scientific meanings of the data contained in the astronomical tables. Essentially two versions of UCDs have been developed: the initial version (UCD1) created at CDS, which uses atomic words separated by underscores (e.g. POS_EQ_RA_MAIN); and a more flexible one, UCD1+ [4], developed in the frame of the *Semantics* group, which uses a reduced vocabulary of dot-separated atoms which can be combined with semi-colons (e.g. pos.eq.ra;meta.main). UCD1+ usage is recommended, but applications using the older vocabulary are still acceptable by this version of VOTable.

A few typical examples of UCD1+ definitions are:

"phot.mag;em.opt.B"	Blue magnitude
"src.orbital.eccentricity"	Orbital eccentricity
"time.period;stat.median"	Median Value of the Period
"instr.det.qe"	Detector's Quantum Efficiency

4.6 The `utype` attribute

In many contexts, it is important to specify that `FIELDs` or `PARAMeters` do convey the values defined in an external *data model*. For instance, it can be fundamental for an application to be aware that a given `FIELD` expresses *the* surface brightness measured with a specific filter and within a 12x6arcsec elliptical aperture. None of the other `name`, `ID` or `ucd` attributes can fill this role, and the `utype` (usage-specific or *unique* type) attribute has been introduced in VOTable 1.1 to fill this gap. By extension, most elements may refer to some external data model, and the `utype` attribute is legal also in `RESOURCE`, `TABLE` and `GROUP` elements.

In order to avoid name collisions, the data model identification should be introduced following the XML namespace conventions, as `utype="datamodel.identifier:role_identifier"`. The mapping of "`datamodel_identifier`" to an xml-type attribute is recommended, by means of the `xmlns` convention which specifies the URI of the data model quoted, as done in the example of section 3.1.

The `utype` attribute is especially useful to specify the *spatial and temporal coordinates* present in the table when it contains astronomical events: these parameters are essential to most applications which process multi-wavelength data. Within the IVOA, the spatial and temporal frames are described in the `STC` data model (see Rots [9]), and it is expected that this *STC*-referencing replaces the usage of the `COOSYS` defined in the version 1.0 of VOTable.

The example given above (see section 3.1) gives an illustration of the recommended way of linking a VOTable document to the `STC` model. Other examples and details are presented in the dedicated note "*Referencing STC in VOTable*" [8].

4.7 `VALUES` element

The `VALUES` element of the `FIELD` is designed to hold subsidiary information about the *domain* of the data. For instance, in the example (section 3.1) we could rewrite the RA field definition as:

```

<FIELD name="RA" ID="col1" ucd="pos.eq.ra;meta.main" ref="J2000"
  utype="stc:AstroCoords.Position2D.Value2.C1"
  datatype="float" width="6" precision="2" unit="deg">
  <VALUES ID="RAdomain">
    <MIN value="0"/>
    <MAX value="360" inclusive="no"/>
  </VALUES>
</FIELD>

```

The scope of the domain described by the **VALUES** element (and by its **MIN**, **MAX** and **OPTION** sub-elements) can be qualified by `type="actual"`, if it is valid only for the data enclosed in the parent **TABLE**; the default `type="legal"` qualification specifies the generic domain of valid values, as in the *RAdomain* in the example above where the interval $[0, 360[$ is specified.

The **VALUES** element may contain **MIN** and **MAX** elements, and it may contain **OPTION** elements; the latter may itself contain more **OPTION** elements, so that a hierarchy of keyword-values pairs can be associated with each field. Note that a single pair **MIN** / **MAX** only is possible, whereas many **OPTION** elements may be found to qualify the domain described by the **VALUES** element. The domain may therefore be defined as a single interval, or as a set of individual values. Although the schema does not forbid all three **MIN**, **MAX** and **OPTION** sub-elements simultaneously, such an usage is considered as bad practice and is discouraged.

All three **MIN**, **MAX** and **OPTION** sub-elements store their value corresponding to the minimum, maximum, or “special value” in a `value` attribute. **MIN** and **MAX** elements can have an `inclusive` attribute to specify whether the `value` quoted belongs or not to the domain, and the **OPTION** element can have a `name` attribute to qualify the “special” quoted `value`.

The **VALUES** element may also have a `null` attribute to define a non-standard value that is used to specify “non-existent data” – for example `null="-32768"`. When this value is found in the corresponding data, it is assumed that no data exists for that table cell; the parser may choose to use this also when unparseable data is found, and the null value will be substituted instead.

The representation of *null* values in the **TABLEDATA** serialisation are indicated in section 6 for each of the primitive data types. Some of the primitive data types have one or more representations of the *null* value (for the “char”, “float” and “double” types, an empty cell may be used). Other types (“boolean”, “unsignedByte”, “short”, and “int”) have no default *null* value defined, and thus, when they are needed, they must be defined explicitly via the **VALUES** element.

For the **FITS** and **BINARY** data representations, the *NaN* (not-a-number) patterns are recommended to represent floating-point *null* values. The *null* convention is therefore only necessary for primitive types that do not have a natural *null* value: long, int, short, and byte datatypes.

Finally the `ref` attribute of a **VALUES** element can be used to avoid a repetition of the domain definition, by referring to a previously defined **VALUES** element having the referenced `ID` attribute. When specified, the `ref` attribute defines completely the domain without any other element or attribute, as e.g. `<VALUES ref="RAdomain"/>`

4.8 INFO element

The **INFO** element is a **PARAM** element restricted of *string* (i.e. `datatype="char"` and `arraysize="*" are implied`). It *must* also have a `name` attribute, and *may* have the other attributes allowed in a **PARAM**: `ID`, `ref`, `unit`, `ucd` and `utype`. But unlike **PARAM**, **INFO** does not accept sub-elements: only text is acceptable in **INFO**’s body. This limitation ensures full compatibility with the previous versions of VOTable.

INFO is meant to convey informative details about the generation of the VOTABLE document. It may be present at the beginning or end of a **VOTABLE** or **RESOURCE** elements, or at the end of a **TABLE**. Typical usages of **INFO** include error reports, or explanations about choices made by the data processing system which generates the VOTable document.

4.9 GROUPing FIELDS and PARAMETERS

The **GROUP** element was introduced in VOTable 1.1, to group together a set of **FIELDS** which are logically connected, like a value and its error. However, in order to avoid any confusion with the first version of VOTable which did not know the **GROUP**, all **FIELDS** are always defined *outside* any group, and the **GROUP** designates its member fields via **FIELDref** elements.

A simple example of a group made of the velocity and its error, based on the example of section 3.1, can be the following:

```
<GROUP name="Velocity">
  <DESCRIPTION>Velocity and its error</DESCRIPTION>
  <FIELDref ref="col4"/>
  <FIELDref ref="col5"/>
</GROUP>
```

The **GROUP** element can have the **name**, **ID**, **ucd**, **utype** and **ref** attributes. It can include a **DESCRIPTION**, and any mixture of **FIELD**references, **PARAM**eters, **PARAM**references and other **GROUP**s. **PARAM**ref is a *logical* definition of a parameter by referring to a **PARAM** element defined elsewhere in the parent **TABLE** or **RESOURCE**, in a way similar to the **FIELD**ref element defined by referring to a **FIELD** element defined elsewhere in the parent **TABLE**. The recursivity of the **GROUP** element enables a definition of arbitrary complex structures.

The possibility of adding **PARAM**eters in groups introduces also a possibility of associating parameter(s) to describe accurately the context of the data stored in the table: for instance, it is possible to associate the actual frequency of a radio survey with the following declaration:

```
<FIELD name="Flux" ID="col4" ucd="phot.flux;em.radio.200-400MHz"
  datatype="float" width="6" precision="1" unit="mJy"/>
<FIELD name="e_Flux" ID="col5" datatype="float" width="4" precision="1"
  ucd="stat.error;phot.flux;em.radio.200-400MHz" unit="mJy"/>
<GROUP name="Flux" ucd="phot.flux;em.radio.200-400MHz">
  <DESCRIPTION>Flux measured at 352MHz</DESCRIPTION>
  <PARAM name="Freq" ucd="em.freq" unit="MHz" datatype="float"
    value="352"/>
  <FIELDref ref="col4"/>
  <FIELDref ref="col5"/>
</GROUP>
```

Similarly, the **GROUP** can be used to associate several parameters to one or several **FIELD**s: a filter may for instance be characterized by the central wavelength and the FWHM of its transmission curve; or several parameters of an instrument setup may be detailed.

4.10 The relational context

With a simple naming convention, the **GROUP** element may also specify some properties of the tables included in a VOTable document when a **TABLE** is viewed as a *relation* (part of a relational data-base):

- a **GROUP** element having the **name**="primaryKey" attribute defines the *primary key* of the relation by enumerating the ordered list of **FIELD**refs that make up the *primary key* of the table;
- a **GROUP** element having the **name**="foreignKey" attribute, with a **ref**="table.reference" reference of the table having the associated primary key, similarly enumerates the **FIELD**refs of the *foreign key*;
- a **GROUP** element having the **name**="order" attribute may specify how the data are ordered.

Similar conventions could well be added for the existence of indexes, unique values, etc...

5 Data Content

While the bulk of the metadata of a VOTable document is in the **FIELD** elements, the data content of the table is in a single **DATA** element. The data is organized in “reading” order, so that the content of each row appears in the same order as the order of the **FIELD** definitions.

Each **DATA** part of the VOTable document can be viewed as a stream coming out of a pipeline. The abstract table is first serialized by one of several methods, then it may be encoded for compression or other reasons. The result may be embedded in the XML file (*local* data), or it may be *remote* data.

Figure 1 shows how the abstract table is rendered into the VOTable document. First the data is *serialized*, either as XML, a FITS binary table, or the VOTable Binary format. This data stream may then be *encoded*, perhaps for

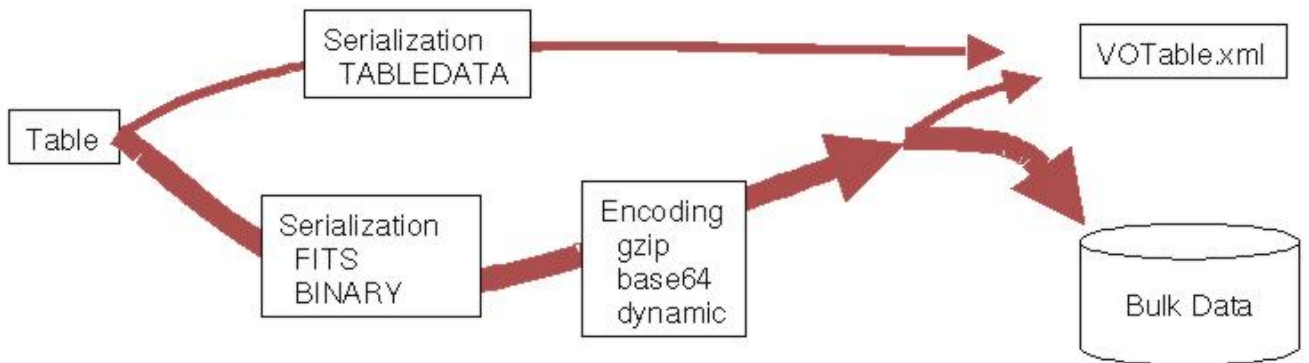

Figure 1: Data serialization

compression or to convert binary to text. Finally, the data stream may be put in a remote file with a URL-type pointer in the VOTable document; or the table data may be embedded in the VOTable. The serialization elements and their attributes are described in the next sections.

5.1 TABLEDATA Serialization

The **TABLEDATA** element is a way to build the table in pure XML, and has the advantage that XML tools can manipulate and present the table data directly. The **TABLEDATA** element contains **TR** elements, which in turn contain **TD** elements — i.e. the same conventions as the familiar *HTML* ones. The number of **TD** elements in each **TR** element must be equal to the number of **FIELD** elements declaring the table. An example is contained in section 3.1, surrounded by in the `<TABLEDATA>` and `</TABLEDATA>` delimiters.

Each item in the **TD** tag contains a value which must be compatible with the **datatype** attribute of the corresponding **FIELD** definition. If the value is the same as the **null** value for that field, then the item is assumed to contain no data. Valid representations of values in a cell, depending on their **datatype**, are detailed in section 6.

If a cell contains an array of numbers or a complex number, it should be encoded as multiple numbers separated by whitespace. However in the case of character and Unicode strings (declared in the corresponding **FIELD** as an array of *char* or *unicodeChar* datatype), no separator should exist. Here is an example of a table with a two rows, that has arrays in the table cells:

```
<TABLE>
  <FIELD ID="aString" datatype="char" arraysize="10"/>
  <FIELD ID="Floats" datatype="float" arraysize="3"/>
  <FIELD ID="varComplex" datatype="floatComplex" arraysize="*"/>
  <DATA><TABLEDATA>
    <TR>
      <TD>Apple</TD><TD>1.62 4.56 3.44</TD>
      <TD>67 1.57 4 3.14 77 -1.57</TD>
    </TR><TR>
      <TD>Orange</TD><TD>2.33 4.66 9.53</TD>
      <TD>39 0 46 3.14</TD>
    </TR>
  </TABLEDATA></DATA>
</TABLE>
```

The first entry is a fixed-length array of 10 characters; since the value being presented (**Apple**) has 5 characters, this is padded with trailing blanks. The second cell is an array of three floats. The last cell contains a variable

array of complex numbers, each complex number being represented by its real part followed by at least a blank and its imaginary part – hence 6 numbers for 3 complex numbers, or 4 numbers for 2 complex numbers.

A special notice should be mentioned about the significance of *white space* in a table cell (the term *whiteSpace* designates the characters *space* [x20], *tab* [x09], *newline* [x0a], *carriage-return* [x0d]): while for numeric data types the amount of white spaces does not matter (the elements of an array of numbers may for instance be written on several lines), the white space is significant for "char" or "unicodeChar" datatypes, and for instance `<TD>Apple</TD>` and `<TD> Apple</TD>` are *not* identical.

5.2 FITS Serialization

The FITS format for binary tables [2] is in widespread use in astronomy, and its structure has a major influence on the VOTable specification. Metadata is stored in a header section, followed by the data. The metadata is substantially equivalent to the metadata of the VOTable format. One important difference is that VOTable does not require specification of the number of rows in the table, an important freedom if the table is being created dynamically from a stream.

The VOTable specification does not define the behavior of parsers with respect to this doubling of the metadata. A parser may ignore the FITS metadata, or it may compare it with the VOTable metadata for consistency, or other possibilities.

The following code shows a fragment that might have been created by a FITS-to-VOTable converter. Each FITS keyword has been converted to a **PARAM**, and the data itself is remotely stored and gzipped at an ftp site:

```
<RESOURCE>
  <PARAM name="EPOCH" datatype="float" value="1999.987">
    <DESCRIPTION> Original Epoch of the coordinates</DESCRIPTION>
  </PARAM>
  <PARAM name="TELESCOP" datatype="char" arraysize="*" value="VTel" />
  <INFO name="HISTORY">
    The very first Virtual Telescope observation made in 2002
  </INFO>
  <TABLE>
    <FIELD (insert field metadata here) />
    <DATA><FITS extnum="2">
      <STREAM encoding="gzip" href="ftp://archive.cacr.caltech.edu/myfile.fit.gz"/>
    </FITS></DATA>
  </TABLE>
</RESOURCE>
```

The FITS file may contain many data objects (known as extensions, numbered from 1 up, the main header being numbered 0), and the **extnum** attribute allows the VOTable to point to one of these.

5.3 BINARY Serialization

The binary format is intended to be easy to read by parsers, so that additional libraries are not required. It is just a sequence of bytes, the length of each sequence corresponding to the **datatype** and **arraysize** attributes of the **FIELD** elements in the metadata. The binary format consists of a sequence of records, with no header bytes, no alignment considerations, no block sizes. The order of the bytes in multi-byte primitives (e.g. integers, floating-point numbers) is Most Significant Byte first, i.e. it follows the FITS convention.

Table cells may contain arrays of primitive types, each of which may be of fixed or variable length. In the former case, the number of bytes is the same for each instance of the item, as specified by the **arraysize** attribute of the **FIELD**. If all the fields have a fixed **arraysize**, then each record of the binary format has the same length (the sum of **arraysize** times the length in bytes of the corresponding **datatype**).

Variable-length arrays of primitives are preceded by a 4-byte integer containing the number of items of the array. The way the stream of bytes is arranged for the data of the example in section 5.1 is illustrated in Figure 2. The parser can then compute the number of bytes taken by the variable-length array by multiplying the size and number of the primitives.

Figure 2: Data Storage in BINARY mode

5.4 Data Encoding

As a result of the serialization, the table has been converted to a byte stream, either text or binary. If the **TABLEDATA** serialization is used, then the table is represented as XML tags directly embedded in the document, and conventional tools can be used to encode the entire XML document. However, VOTable also provides limited encoding of its own. A VOTable document may point to a remote data resource that is compressed; rather than decompressing before sending on the wire, it can be dynamically decoded by the VOTable reader. We might also use the encoding facilities to convert a binary file to text (through base64 encoding), so that binary data can be used in the XML document.

In this version (1.2) of VOTable, it is not possible to encode individual columns of the table: the whole table must be encoded in the same way. The possibility of encoding selected table cells is however being examined for future versions of VOTable (see appendix A.5).

In order to use an encoding of the data, it must be enclosed in a **STREAM** element, whose attributes define the nature of the encoding. The **encoding** attribute is a string that should indicate to the parser how to undo the encoding that has been applied. Parsers should understand and interpret at least the following values:

- **encoding="gzip"** [RFC1952] implies that the data following has been compressed with the *gzip* filter, so that *gunzip* or similar should be applied.
- **encoding="base64"** [RFC2045] implies that the *base64* filter has been applied, to convert binary to text.
- **encoding="dynamic"** implies that the data is in a remote resource (see below), and the encoding will be delivered with the header of the data. This occurs with the http protocol, where the MIME header indicates the type of encoding that has been used.

The default value of the encoding attribute is the null string, meaning that no encoding has been applied. In future releases, we might allow more complex strings in the encoding attribute, allowing combinations of encoding filters and a way for the parser to find the software needed for the decoding.

5.5 Remote Data

If the encoding of the data produces text, or if the serialization is naturally text-based, then it can be directly embedded into the XML document, as for instance:

```
<DATA><BINARY>
<STREAM encoding="base64">
AAAAAJ/yVZiDGSSUwFZ6ypR4yGkADwAcQVOeuAAIAAJBmMzNwZWZmkG1e4tBR3jVQT9ocwAA
.....
```

```
</STREAM>
</BINARY></DATA>
```

However, if the data is very large, it may be preferable to keep the data separate from the metadata. The `href` attribute of the `STREAM` element, if present, provides the location of the data in a URL-type syntax, for example:

```
<STREAM href="ftp://server.com/mydata.dat"/>
<STREAM href="ftp://server.com/mydata.dat" expires="2004-02-29T23:59:59"/>
<STREAM href="http://server.com/mydata.dat" actuate="onLoad"/>
<STREAM href="file:///usr/home/me/mydata.dat"/>
```

The examples are the well-known anonymous ftp, and http protocols. "`http`" is an example of a Grid-based access to data through `http`; finally, "`file`" is a reference to a local file. VOTable parsers are not required to understand arbitrary protocols, but are required to understand the three common protocols "`file`", "`http`" and "`ftp`".

There are further attributes of the `STREAM` element that may be useful. The `expires` attribute indicates the expiration time of the data: this is useful when data are dynamically created and stored on some staging disk where files only persist for a specified lifetime and are then automatically deleted. The `expires` attribute expresses when a remote resource ceases to become valid, and is expressed in Universal Time in the same way as the FITS specification [2], itself conforming to the ISO 8601 standard.

The `rights` attribute expresses authentication information that may be necessary to access the remote resource. If the VOTable document is suitably encrypted, this attribute could be used to store a password.

The `actuate` attribute is borrowed from the XML Xlink specification, expressing when the remote link should be actuated. The default is "`onRequest`", meaning that the data is only fetched when explicitly requested (like a link on an HTML page), and the "`onLoad`" value means that data should be fetched as soon as possible (like an embedded image on an HTML page).

6 Definitions of Primitive Datatypes

This section describes the primitives summarized in Table 1 and their representations in the `BINARY` and in the `TABLEDATA` serializations (see section 5.1). In the following, the term "hexadigit" designates the ASCII numbers "0" to "9", or the ASCII lower- or upper-case letters "a" to "f" (i.e. a digit in an hexadecimal representation of a number).

- **Logical** If the value of the `datatype` attribute specifies data type "`boolean`", the contents of the field shall consist in the `BINARY` serialization of ASCII "`T`", "`t`", or "`1`" indicating true, ASCII "`F`", "`f`", or "`0`" indicating false; the *null* value is indicated by an ascii NULL [0x00], a space [0x20] or a question mark "?" [0x3f]. The acceptable representations in the `TABLEDATA` serialization include in addition any capitalisation variation of the strings "`true`" and "`false`" (e.g. "`tRUe`" or "`FalsE`"); the default representation of a *null* value is an empty cell (see section 4.7)
- **Bit Array** If the value of the `datatype` attribute specifies data type "`bit`", the contents of the field in the `BINARY` serialization shall consist of a sequence of bits starting with the most significant bit; the bits following shall be in order of decreasing significance, ending with the least significant bit. A bit field shall be composed of the smallest number of bytes that can accommodate the number of elements in the field. Padding bits shall be 0. The representation of a bit array in the `TABLEDATA` serialization is made by a sequence of ASCII "0" and "1" characters.
- **Byte** If the value of the `datatype` attribute specifies data type "`unsignedByte`", the field shall contain in the `BINARY` serialization a byte (8-bits) representing a number in the range 0 to 255. In the case of an array of bytes (`arraysize="*"`), also known as a "blob", the bytes are stored consecutively. The representation of a Byte in the `TABLEDATA` serialization can be its *decimal* representation (a number between 0 and 255) or its *hexadecimal* representation when starting by 0x and followed by one or two hexadigits, (e.g. `0xff`), separated by at least one space from the next one in the case of an array of bytes. No default *null* value exists; if necessary one has to be defined via the `null` attribute of the `VALUES` element (section 4.7).
- **Character** If the value of the `datatype` attribute specifies data type "`char`", the field shall contain in the `BINARY` serialization an ASCII (7-bit) character. The `arraysize` attribute indicates a character string composed of ASCII text. The `BINARY` serialization follows the FITS rules for character strings, and a character

string may therefore be terminated by an ASCII NULL [0x00] before the length specified in the `arraysize` attribute: in this case characters after the first ASCII NULL are not defined; and a string having the number of characters identical to the `arraysize` value is not NULL terminated. Characters should be represented in the `TABLEDATA` serialization using the normal rules for encoding XML text: the ampersand (&) can be written `&`; (symbolic representation) or `&`; (decimal representation) or `&`; (hexadecimal representation); the less-than (<) and greater-than (>) symbols should be coded `<`; and `>`; or `<`; and `>`; notice also the significance of the *white space* characters in the `TABLEDATA` serialization (section 5.1)

- **Unicode Character** If the value of the `datatype` attribute specifies data type "unicodeChar", the field shall contain a Unicode character. The `arraysize` attribute indicates a string composed of Unicode text — which enables representation of text in many non-Latin alphabets. Each Unicode character is represented in the `BINARY` serialization by two bytes, using the big-endian UCS-2 encoding (ISO-10646-UCS-2). The representation of a Unicode character in the `TABLEDATA` serialization follows the XML specifications, and e.g. the Cyrillic uppercase “Ya” can be written `Я` in UTF-8. Notice also the significance of the *white space* characters in the `TABLEDATA` serialization (section 5.1)
- **16-Bit Integer** If the value of the `datatype` attribute specifies datatype "short", the data in the `BINARY` serialization shall consist of big-endian twos-complement signed 16-bit integers (the most significant byte first). The representation of a Short Integer in the `TABLEDATA` serialization is either its decimal representation between -32768 and 32767 made of an optional - or + sign followed by digits, or its hexadecimal representation when starting by 0x and followed by 1 to 4 hexadigits. No default *null* value exists; if necessary one has to be defined via the `null` attribute of the `VALUES` element (section 4.7).
- **32-Bit Integer** If the value of the `datatype` attribute specifies datatype "int", the data in the `BINARY` serialization shall consist of big-endian twos-complement signed 32-bit integer — contained in four bytes, with the most significant first, and subsequent bytes in order of decreasing significance. The representation of an Integer in the `TABLEDATA` serialization is either its decimal representation between -2147483648 and 2147483647 made of an optional - or + sign followed by digits, or its hexadecimal representation when starting by 0x and followed by 1 to 8 hexadigits; No default *null* value exists; if necessary one has to be defined via the `null` attribute of the `VALUES` element (section 4.7).
- **64-Bit Integer** If the value of the `datatype` attribute specifies datatype "long", the data in the `BINARY` serialization shall consist of big-endian twos-complement signed 64-bit integers — contained in eight bytes, with the most significant byte first, and subsequent bytes in order of decreasing significance. The representation of a Long Integer in the `TABLEDATA` serialization is either its decimal representation between -9223372036854775808 and 9223372036854775807 made of an optional - or + sign followed by digits, or its hexadecimal representation when starting by 0x and followed by 1 to 16 hexadigits; No default *null* value exists; if necessary one has to be defined via the `null` attribute of the `VALUES` element (section 4.7).
- **Single Precision Floating Point** If the value of the `datatype` attribute specifies datatype "float", the data in the `BINARY` serialization shall consist of ANSI/IEEE-754 32-bit floating point numbers in big-endian order. All IEEE special values are recognized. The IEEE NaN pattern is used to represent *null* values. The representation of a Floating Point number in the `TABLEDATA` serialization is made of an optional - or +, followed by the ASCII representation of a positive decimal number, and followed eventually by the ASCII letter "E" or "e" introducing the base-10 exponent made of an optional - or + followed by 1 or 2 digits. The number must be within the limits of the IEEE floating-point definition (around $\pm 3.4 \cdot 10^{38}$; numbers with absolute value less than about $1.4 \cdot 10^{-45}$ are equated to zero); the default representation of a *null* value is an empty cell (see section 4.7), and the special values "+Inf", "-Inf", and "NaN" are accepted.
- **Double Precision Floating Point** If the value of the `datatype` attribute specifies datatype "double", the data in the `BINARY` serialization shall consist of ANSI/IEEE-754 64-bit double precision floating point numbers in big-endian order. All IEEE special values are recognized. The IEEE NaN pattern is used to represent *null* values. The representation of a Double number in the `TABLEDATA` serialization is made of an optional - or +, followed by the ASCII representation of a positive decimal number, and followed eventually by the ASCII letter "E" or "e" introducing the base-10 exponent made of an optional - or + followed by 1 to 3 digits. The number must be within the limits of the IEEE floating-point definition (around $\pm 1.7 \cdot 10^{308}$; numbers with absolute value less than about $5 \cdot 10^{-324}$ are equated to zero); the default representation of a *null* value is an empty cell (see section 4.7), and the special values "+Inf", "-Inf", and "NaN" are accepted.
- **Single Precision Complex** If the value of the `datatype` attribute specifies datatype "floatComplex", the data in the `BINARY` serialization shall consist of a sequence of pairs of 32-bit single precision floating point numbers in big-endian order. The first member of each pair shall represent the real part of a complex

number and the second member shall represent the imaginary part of that complex number. If either member contains a NaN, the entire complex value is *null*. The representation of a Floating Complex number in the **TABLEDATA** serialization is made of two representations of a *Single Precision Floating Point* numbers separated by whitespace, representing the real and imaginary part respectively; the default representation of a *null* value is an empty cell (see section 4.7).

- **Double Precision Complex** If the value of the **datatype** attribute specifies datatype "doubleComplex", the data in the **BINARY** serialization shall consist of a sequence of pairs of 64-bit double precision floating point numbers in big-endian order. The first member of each pair shall represent the real part of a complex number and the second member of the pair shall represent the imaginary part of that complex number. If either member contains a NaN, the entire complex value is *null*. The representation of a Double Complex number in the **TABLEDATA** serialization is made of two representations of a *Double Precision Floating Point* numbers separated by whitespace, representing the real and imaginary part respectively; the default representation of a *null* value is an empty cell (see section 4.7).

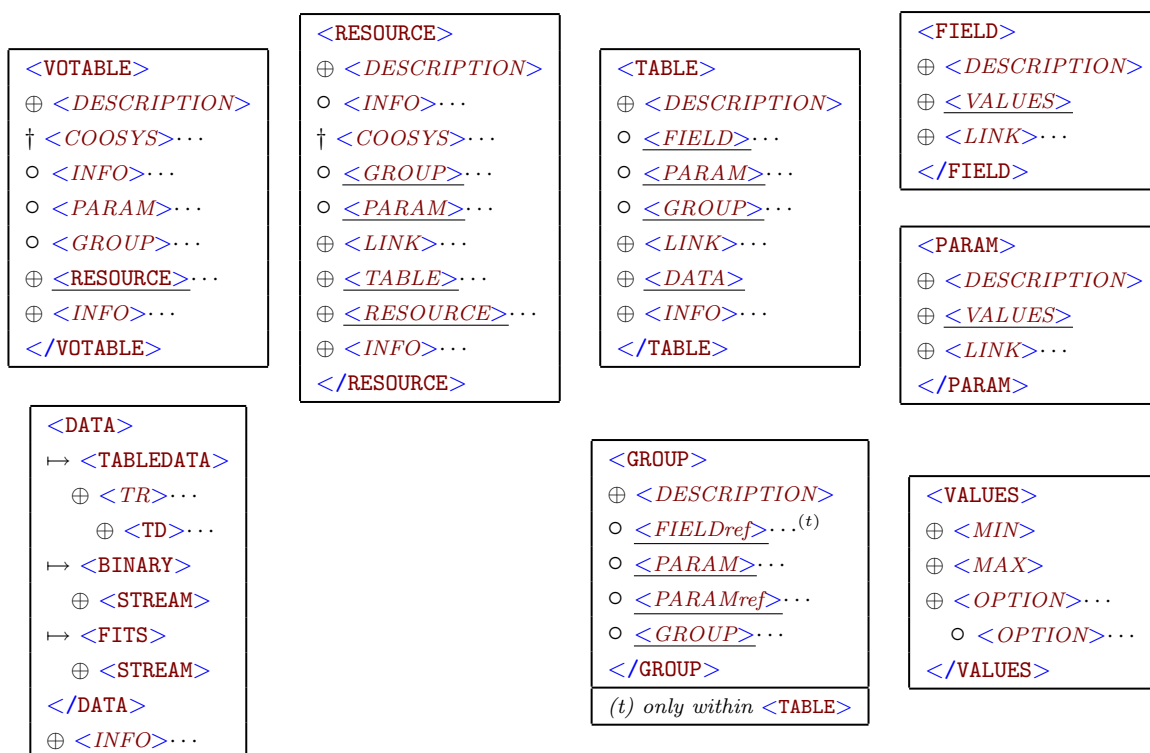

7 A simplified view of the VOTable 1.2 Schema

The XML Schema [7] defining a VOTable 1.2 document is available from <http://www.ivoa.net/xml/VOTable/v1.2> In this section we illustrate this XML Schema by a set of boxes describing the structure of a VOTable, and the list of attributes of each VOTable element.

7.1 Element Hierarchy

The hierarchy of the elements existing in VOTable-1.2 is illustrated below; it uses the following conventions:

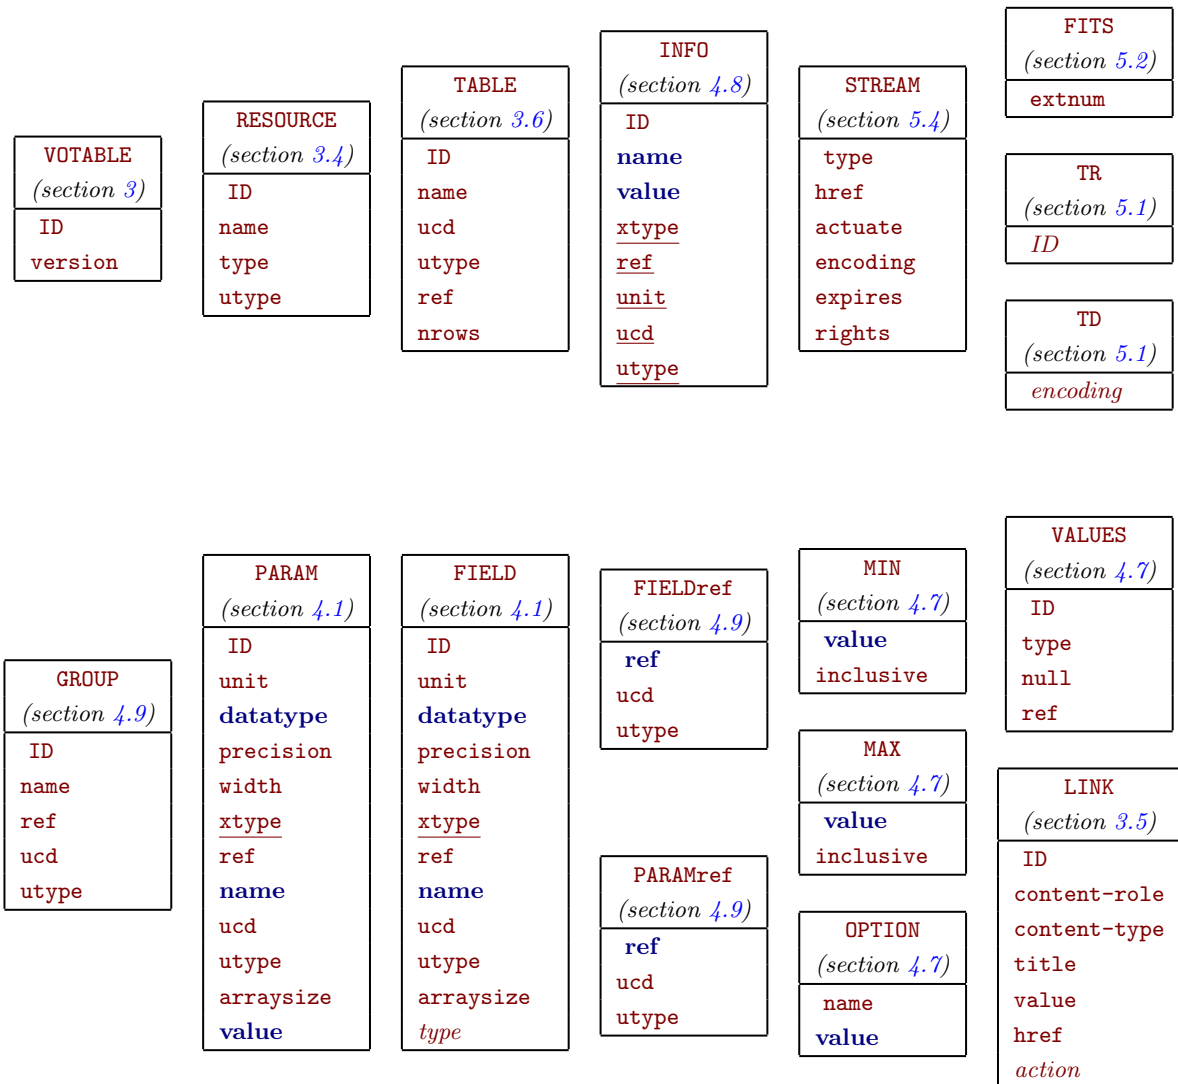

- *italicized* text represents *optional* elements;
- ⊕ indicates that the order of the elements is mandatory, while
- ○ (*open bullet*) indicates that the corresponding elements may occur in any order;
- ↦ marks a choice between alternatives.
- † marks a *deprecated* element (valid in Version 1.1, discouraged in Version 1.2)
- ... (dots) indicate that an element may be repeated.
- underlined elements may contain sub-elements, and are therefore explained in a dedicated box of the figure.

7.2 Attribute summary

The list of the attributes is summarized in the table below, with the following conventions:

- attributes written in bold are **required attributes**
- attributes written in a fixed font are **optional**.
- attributes written in *italics* are not part of VOTable 1.2, but are *reserved* for possible extensions (mentioned in an Appendix).
- attributes added in VOTable1.2 are underlined

7.3 Mime type

Finally, a VOTable document should be introduced by a *mime type* (Multipurpose Internet Mail Extensions, defined in the RFC 2046): associating a mime type to a document enables the *data consumer* (an application or a web browser) to launch the desired application (*e.g.* a visualisation tool).

In the HTTP protocol, the mime type is the value specified by the Content-Type: line. The recommended mime-type describing a VOTable document is `application/x-votable+xml`: the `x-` prefix indicates an experimental type, and is required for non-registered media types; and the `+xml` suffix (defined by RFC 3023 section 7) indicates that the type describes a specialization of XML.

However the `text/xml` mime type is acceptable for services delivering data which are expected to be visualized by humans in a browser; this mime type would preferably be associated with an XSL style sheet, for a presentation of well-formatted tables. It is expected that a few typical XSL style sheets will be accessible from the IVOA site.

8 Differences between versions 1.1 and 1.2

The differences between version 1.2 of VOTable and the preceding version 1.1 are:

- the **COOSYS** is deprecated, in favor of a reference to the *Space-Time Coordinate* (STC) data model (see section 4.6 and the IVOA note *Referencing STC in VOTable*[8])
- the **GROUP** may appear as a direct child of **VOTABLE** and **RESOURCE** (where *COOSYS* was acceptable)

- the usage of UCD1+ is recommended (section 4.5)
- the **xtype** attribute was added (see section 4.3)
- the **INFO** element (section 4.8) is made more similar to the **PARAM** element, but with **datatype="char"** and **arraysize="*"** (i.e. is a *String*): may have attributes **utype**, **ucd**, **ref**, **unit**
- the **INFO** element may occur before the closing tags **/TABLE** and **/RESOURCE** and **/VOTABLE** (enable *post-operational diagnostics*)
- the **FIELDref** and **PARAMref** elements may have a **utype** and **ucd** attribute.
- naming conventions of **GROUP** elements which specify some properties of a relational schema (see section 4.10).
- explicitation of the recommended and acceptable mime types (section 7.3)
- explicitation of arrays in cells (section 2.2)
- detailed and clarified the conventions and recommendations concerning **name**, **ID** and **ref** attributes
- the appendix A7 was a proposition for additional **utype** attributes in groups and tables; it is now included in VOTable1.2. The appendix A.7 now contains a new proposal (May/June 2009) for multiple descriptions and titles.

Appendices

A Possible VOTable extensions

The definitions enclosed in this appendix are **not** part of VOTable 1.1, but are considered as candidates for VOTable improvements.

A.1 VOTable LINK substitutions

The LINK element in Astrores [1] contains a mechanism for string substitution, which is a powerful way of defining a link to external data which adapts to each record contained in the table DATA.

When a **LINK** element appears within a **RESOURCE** or a **TABLE** element, extra functionality is implied: the **href** attribute may not be a simple link, but instead a template for a link. If, in the example of section 3.1, we add the link

```
<LINK href="http://ivoa.net/lookup?Galaxy=${Name}&RA=${RA}&DE=${DE}"/>
```

a substitution filter is applied in the context of a particular row. For the first row of the table, the substitution would result in the URL

```
http://ivoa.net/lookup?Galaxy=N%20224&RA=010.68&DE=%2b41.27
```

Whenever the pattern `${...}` is found in the original link, the part in the braces is compared with the set of **ID** (preferably) or **name** attributes of the fields of the table. If a match is found, then the value from that field of the selected row is used in place of the `${...}`. If no match is found, no substitution is made. Thus the parser makes available to the calling application a value of the **href** attribute that depends on which row of the table has been selected. Another way to think of it is that there is not a single link associated with the table, but rather an implicitly defined new column of the table. This mechanism can be used to connect each row of the table to further information resources.

The purpose of the link is defined by the **content-role** attribute. The allowed values are "query" (see section A.2), "hints" for information for use by the application, and "doc" for human-readable documentation.

The column names invoked in the pattern of the **href** attribute of the **LINK** element should exist in the document to generate meaningful links. In the common case where the VOTable was generated from a query of a database and contains only some of the columns in that database, it might be necessary to include columns additional to those requested in order to ensure that the **LINKS** in the VOTable are operational. Such a **FIELD** included "by necessity" is marked with the attribute **type="hidden"**. The primary key of a relational table is a typical example of a **FIELD** which would carry the **type="hidden"** attribute.

A.2 VOTable Query Extension

The metadata part included in a RESOURCE contains all the details necessary to create a form for querying the resource. The addition of a link having the action attribute can turn VOTable into a powerful query interface.

In Astrores [1], the details on the input parameters available in queries are described by the **PARAM** and **FIELD** elements, and the syntax used to generate the actual query is described in the ASU [6] protocol: the **FIELD** or **PARAM** elements are paired in the form *name=value*, where *name* is the contents of the **name** attribute of a **FIELD** or **PARAM**, and *value* represents a constraint written with the ASU conventions (e.g. "`< 8`" or "`12.0..12.5`" which denotes a range of values). Such pairs are appended to the **action** specified in the **LINK** element contained in the **RESOURCE**, separated by the ampersand (&) symbol – in a way quite similar to the HTML syntax used to describe a **FORM**.

A special **type="no_query"** attribute of the **PARAM** or **FIELD** elements marks the fields which are *not* part of the form, i.e. are ignored in the collection of *name=value* pairs.

The following is an example of a transformation of the VOTable in section 3.1 into a form interface:

```

<?xml version="1.0"?>
<VOTABLE version="1.2" xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
  xmlns="http://www.ivoa.net/xml/VOTable/v1.2"
  xmlns:stc="http://www.ivoa.net/xml/STC/v1.30" >
  <RESOURCE name="myFavouriteGalaxies" type="meta">
    <TABLE name="results">
      <DESCRIPTION>Velocities and Distance estimations</DESCRIPTION>
      <GROUP ID="J2000" utype="stc:AstroCoords">
        <PARAM datatype="char" arraysiz="*" ucd="pos.frame" name="cooframe"
          utype="stc:AstroCoords.coord_system_id" value="UTC-ICRS-TOPO" />
        <FIELDref ref="col1"/>
        <FIELDref ref="col2"/>
      </GROUP>
      <PARAM name="-out.max" ucd="meta.number" datatype="int" value="50">
        <DESCRIPTION>Maximal number of records to retrieve</DESCRIPTION>
      </PARAM>
      <LINK content-role="query" action="myQuery?-source=myGalaxies&amp;" />
      <DESCRIPTION>Velocities and Distance estimations</DESCRIPTION>
      <FIELD name="RA" ID="col1" ucd="pos.eq.ra;meta.main" ref="J2000"
        utype="stc:AstroCoords.Position2D.Value2.C1"
        datatype="float" width="6" precision="2" unit="deg"/>
      <FIELD name="Dec" ID="col2" ucd="pos.eq.dec;meta.main" ref="J2000"
        utype="stc:AstroCoords.Position2D.Value2.C2"
        datatype="float" width="6" precision="2" unit="deg"/>
      <FIELD name="Name" ID="col3" ucd="meta.id;meta.main"
        datatype="char" arraysiz="8*"/>
      <FIELD name="RVel" ID="col4" ucd="spect.dopplerVeloc" datatype="int"
        width="5" unit="km/s"/>
      <FIELD name="e_RVel" ID="col5" ucd="stat.error;spect.dopplerVeloc"
        datatype="int" width="3" unit="km/s"/>
      <FIELD name="R" ID="col6" ucd="pos.distance;pos.heliocentric"
        datatype="float" width="4" precision="1" unit="Mpc">
        <DESCRIPTION>Distance of Galaxy, assuming H=75km/s/Mpc</DESCRIPTION>
      </FIELD>
    </TABLE>
  </RESOURCE>
</VOTABLE>

```

Note that the **RESOURCE** displaying the parameters accessible for a query has the **type="meta"** attribute; it is also assumed that only one **LINK** having the **content-role="query"** attribute together with an **action** attribute exists within the current **RESOURCE**. The **PARAM** with **name="-out.max"** has been added in this example to control the size of the result.

A valid query generated by this VOTable could be:

```
myQuery?-source=myGalaxies&-out.max=50&R=10..100
```

A.3 Arrays of variable-length strings

Following the FITS conventions, strings are defined as arrays of characters. This definition raises problems for the definition of arrays of strings, which have then to be defined as 2D-arrays of characters – but in this case only the slowest-varying dimension (i.e. the number of strings) can be variable. This limitation becomes severe when a table column contains a set of remarks, each being made of a variable number of characters as occurs in practice. FITS invented the *Substring Array* convention (defined in an appendix, i.e. not officially approved) which defines a *separator* character used to denote the end of a string and the beginning of the next one. In this convention (*rA:SSTRw/c*) the total size of the character array is specified by *r*, *w* defines the maximum length of one string, and *c* defines the separator character as its ASCII equivalent value. The possible values for the separator includes the space and any printable character, but excludes the control characters.

Such arrays of variable-length strings are frequently useful e.g. to enumerate a list of properties of an observed source, each property being represented by a variable-length string. A convention similar to the FITS one could

be introduced in VOTable in the **arraysize** attribute, using the **s** followed by the separator character; an example can be **arraysize="100s,"** indicating a string made of up to 100 characters, where the comma is used to separate the elements of the array.

A.4 FIELDS as data pointers

Rather than requiring that all data described in the set of **FIELDS** are contained in a single stream which follows the metadata part, it would be possible to let the **FIELD** act as a *pointer* to the actual data, either in the form of a URI or of a reference to a component of a multipart document.

Each component of the data described by a **FIELD** may effectively have different requirements: while text data or small lists of numbers are quite efficiently represented in pure XML, long lists like spectra or images generate poor performances if these are converted to XML. The method available to gain efficiency is to use a binary representation of the *whole data stream* by means of the **STREAM** element – at the price of delivering data in a totally non-human readable format.

The following options would allow more flexibility in the way the various **FIELDS** can be accessed:

- a **FIELD** can be declared as being a *pointer* with the addition of a **type="location"** value, meaning that the field contains a way to access the data, and not the actual data;
- a **FIELD** can contain a **LINK** element marked **type="location"** which contains in its **href** attribute the partial URI to which the contents of the column cell is appended in order to generate a fully qualified URI.

Note that the **LINK** is not required – a **FIELD** declared with **type="location"** and containing no **LINK** element is assumed to contain URIs.

An example of a table describing a set of spectra could look like the following:

```
<TABLE name="SpectroLog">
  <FIELD name="Target" ucd="meta.id" datatype="char" arraysize="30*" />
  <FIELD name="Instr" ucd="instr.setup" datatype="char" arraysize="5*" />
  <FIELD name="Dur" ucd="time.expo" datatype="int" width="5" unit="s" />
  <FIELD name="Spectrum" ucd="meta.ref.url" datatype="float" arraysize="*"
    unit="mW/m2/nm" type="location">
    <DESCRIPTION>Spectrum absolutely calibrated</DESCRIPTION>
    <LINK type="location"
      href="http://ivoa.spectr/server?obsno=" />
  </FIELD>
  <DATA><TABLEDATA>
    <TR><TD>NGC6543</TD><TD>SWS06</TD><TD>2028</TD><TD>01301903</TD></TR>
    <TR><TD>NGC6543</TD><TD>SWS07</TD><TD>2544</TD><TD>01302004</TD></TR>
  </TABLEDATA></DATA>
</TABLE>
```

The reading program has therefore to retrieve the data for this first row by resolving the URI

```
http://ivoa.spectr/server?obsno=01301903
```

The same method could also be immediately applicable to *Content-IDs* which designate elements of a multipart message, using the protocol prefix **cid**: [RFC2111]

Note that the *VOTable LINK substitution* proposed in section A.1 fills a similar functionality: generate a pointer which can incorporate in its address components from the **DATA** part for the VOTable.

A.5 Encoding individual table cells

Accessing binary data improves quite significantly the efficiency both in storage and CPU usage, especially when one compares with the XML-encoded data stream. But binary data cannot be included in the same stream as the metadata description, unless a dedicated coding filter is applied which converts the binary data into an ASCII representation. The base64 is the most commonly used filter for this conversion, where 3 bytes of data are coded as 4 ASCII characters, which implies an overhead of 33% in storage, and some (small) computing time necessary for the reverse transformation.

In order to keep the full VOTable document in a unique stream, VOTable 1.0 introduced the **encoding** attribute in the **STREAM** element, meaning that the data, stored as binary records, are converted into some ASCII representation compatible with the XML definitions. One drawback of this method is that the entire data contents become non human-readable.

The addition of the **encoding** attribute in the **TD** element allows the data server to decide, at the cell level, whether it is more efficient to distribute the data as binary-encoded or as edited values. The result may look like the following:

```

<TABLE name="SpectroLog">
  <FIELD name="Target" ucd="meta.id" datatype="char" arraysize="30*" />
  <FIELD name="Instr" ucd="instr.setup" datatype="char" arraysize="5*" />
  <FIELD name="Dur" ucd="time.expo" datatype="int" width="5" unit="s" />
  <FIELD name="Spectrum" ucd="phot.flux;em.opt" datatype="float" arraysize="*"
    unit="mW/m2/nm" precision="E3" />
  <DATA><TABLEDATA>
    <TR><TD>NGC6543</TD><TD>SWS06</TD><TD>2028</TD><TD encoding="base64">
      QJKPXECHvndAgMScQHul40CSLQ5ArocrQLxiTkC3XC1Aq00WQKQIMUCb1YFAh753QGij10BT
      Em9ARKwiQExqf0BqbpAieufQJS00UCJWBBAhcrBQJMzMOcmRaJAuRaHQLWZmkCyhytAunbJ
      QLN87kC26X1A1kwiQOu+dODsWh1A5an8QN0m6UD0VgRAx02RQM9Lx0Din75A3o9cQMPf00C/
      dLxAvUeuQKN87kCXQ5ZAjFodQH0vG0B/jVBAgaHLQI7Ag0CiyLRAqBBiQLaXjUDYcrBA8p++
      QPcKPUDg7ZFAwckPQLafvkDD1YFA1T99QM2BBkCs3S9AjlXqQISDEkC06X1Am1YEQKibpkC5
      wo9AvKPXQLGBBkCs9cNAuGp/QL0euEC4crBAuR64QL6PXED0TdNA2987QN9T+EDoMSdA8mZm
      QOZumEDDZfPammZmG1YEEBa4UhaivGqQLel140Dgan9A4WBCQLNcKUCIKPZAk1P4QNWRaEEP
      kWhBKahlQTKOVkFEan9BUWBCQVfvg==
    </TD></TR>
  </TABLEDATA></DATA>
</TABLE>

```

When decoded, the contents of the last column is the binary representation of the spectrum, as defined in section 5.3; no length prefix is required here, the total length of the array being implicitly defined by the length of the encoded text.

A.6 Very large arrays

The **BINARY** serialization of variable-length arrays (section 5.3) uses a 4-byte prefix containing the number of items of the array. This convention imposes an absolute maximal number of $2^{31} - 1$ elements. This limit could be released with a new **arrayprefix** attribute.

A.7 Additional descriptions and titles

The same table may be used in several contexts, and it was for instance expressed a wish to include in **TABLE** and **FIELD** descriptions and titles (captions) in a form suitable for a publication (latex) in addition to the ascii-only descriptions currently acceptable. The following example is an illustration of this extension:

```

<TABLE name="Model_A">
  <DESCRIPTION>Star luminosities in Model A</DESCRIPTION>
  <DESCRIPTION context="latex">$L(T_{\text{eff}})$ in Model {\bf A}</DESCRIPTION>
  <FIELD name="Teff" datatype="float" unit="K" ucd="phys.temperature.effective">
    <DESCRIPTION>Effective temperature</DESCRIPTION>
    <TITLE context="latex">$T_{\text{eff}}$</TITLE>
  </FIELD>
  <FIELD name="Lum" datatype="float" unit="Lsun" ucd="phys.luminosity">
    <DESCRIPTION>Corresponding luminosity in Model A</DESCRIPTION>
    <DESCRIPTION context="latex">$L(T_{\text{eff}})$</DESCRIPTION>
    <TITLE context="latex">$L/L_{\odot}$</TITLE>
  </FIELD>
</TABLE>

```

In practice this extension would mean that, wherever a **DESCRIPTION** element is currently acceptable, a set of **DESCRIPTION** and **TITLE** elements would become acceptable, each with an optional **context** additional attribute. The new **TITLE** element would have the role of expliciting the *column header* in a field or parameter, or to supply a *caption* of a table or a set of tables (resource) in addition to its description.

Providing descriptions in several languages would be another obvious advantage of this extension.

A.8 A new XMLDATA serialization

In order to facilitate the use of standard XML query tools which usually require each parameter to have its own individual tag, the **XMLDATA** serialization introduces the designation of each **FIELD** by a dedicated tag. An example could look like the following:

```

<TABLE name="Messier">
  <FIELD name="Number" ID="M" ucd="meta.record" datatype="int" >
    <DESCRIPTION>Messier Number</DESCRIPTION>
  </FIELD>
  <FIELD name="R. A.2000" ID="RA" ucd="pos.eq.ra;meta.main" ref="J2000"
    unit="deg" datatype="float" width="5" precision="1" />
  <FIELD name="Dec.2000" ID="DE" ucd="pos.eq.dec;meta.main" ref="J2000"
    unit="deg" datatype="float" width="5" precision="1" />
  <FIELD name="Name" ID="N" ucd="meta.id" datatype="char" arraysize="*">
    <DESCRIPTION>Common name used to designate the Messier object</DESCRIPTION>
  </FIELD>
  <FIELD ID="T" name="Classification" datatype="char" arraysize="10*"
    ucd="src.class">
    <DESCRIPTION>Classification (galaxy, globular cluster, etc)</DESCRIPTION>
  </FIELD>
  <DATA><XMLDATA>
    <TR>
      <M>3</M>
      <RA>205.5</RA>
      <DE>+28.4</DE>
      <N/>
      <T>Globular Cluster</T>
    </TR>
    <TR>
      <M>31</M>
      <RA>010.7</RA>
      <DE>+41.3</DE>
      <N>Andromeda Galaxy</N>
      <T>Galaxy</T>
    </TR>
  </XMLDATA></DATA>
</TABLE>

```

The full document would need an XML-Schema definition of the tags **M**, **RA**, **DE**, **N** and **T**; these being derived directly from the **ID** attribute of the **FIELD** element, their definition can be generated automatically from the set of **FIELD** definitions.

B The VOTable/v1.2 XML Schema

The XML Schema of VOTable 1.2 is included here as a reference; the date of this schema is 2009-09-29. This schema includes a couple of extra optional attributes which are not part of VOTable-1.2 (*ID* in TR and *encoding* in TD), but proved to be useful to fix some problems encountered in the usage of some code generators.

```

<?xml version="1.0" encoding="UTF-8"?>

<xs:annotation><xs:documentation>
  VOTable1.2 is meant to serialize tabular documents in the
  context of Virtual Observatory applications. This schema
  corresponds to the VOTable document available from
  http://www.ivoa.net/Documents/latest/VOT.html
</xs:documentation></xs:annotation>

<!-- Here we define some interesting new datatypes:
  - anyTEXT may have embedded XHTML (conforming HTML)
  - astroYear is an epoch in Besselian or Julian year, e.g. J2000
  - arrayDEF specifies an array size e.g. 12x23x*
  - dataType defines the acceptable datatypes
  - ucdType defines the acceptable UCDS (UCD1+)
  - precType defines the acceptable precisions
  - yesno defines just the 2 alternatives
-->
